Abstract 22

One or two sentences providing a basic introduction to the field, comprehensible to a

scientist in any discipline.

Two to three sentences of more detailed background, comprehensible to scientists 25

in related disciplines.

One sentence clearly stating the **general problem** being addressed by this particular 27

study. 28

One sentence summarizing the main result (with the words "here we show" or their 29

equivalent).

Two or three sentences explaining what the main result reveals in direct comparison 31

to what was thought to be the case previously, or how the main result adds to previous

knowledge.

One or two sentences to put the results into a more **general context**. 34

Two or three sentences to provide a **broader perspective**, readily comprehensible to 35

a scientist in any discipline.

Keywords: keywords 37

Word count: X 38

A baseline for inferences about human cognitive evolution: structure, stability and predictability of great ape cognition

Introduction

In their quest for understanding the evolution of the human mind, psychologists and 42 cognitive scientists face one major obstacle: cognition does not fossilize. Instead of directly 43 studying the cognitive abilities of our extinct ancestors, we have to rely on backward inferences. We can study fossilized skulls and crania to approximate brain size and structure and use this information to infer cognitive abilities (Coqueugniot, Hublin, Veillon, Houët, & Jacob, 2004; Gunz et al., 2020). We can study the material culture left behind by our ancestors and try to infer its cognitive complexity experimentally (Coolidge & Wynn, 2016; Currie & Killin, 2019; Haslam et al., 2017). Yet, the archaeological record is sparse and only goes back so far in time. Thus, one of the most fruitful approaches to cognitive evolution is the comparative method. By studying extant species of primates, we make backward inferences about the last common ancestor. If species A and B both show cognitive ability X, the last common ancestor of A and B most likely also had ability X (MacLean et al., 2012; Martins & Martins, 1996). To make inferences about the most recent events in human cognitive evolution, we have to study and compare humans and the great apes. Such approach has been highly productive and was the basis for numerous theories about human uniqueness (Heyes, 2018; Laland & Seed, 2021; Penn, Holyoak, & Povinelli, 2008; Tomasello, 57 2019). 58

However, using the comparative method in this way requires a strong great ape
baseline. That is, it takes a solid and robust way of describing the great ape mind in order
to map out how it differs from that of humans. What kind of empirical evidence is required
to infer such a baseline? First, group-level results should be stable. Our inferences about the
cognitive abilities that great apes – as a group – do or do not have do based on the data we
collect today should not change if we repeat the study tomorrow. Second, individual

differences in cognitive abilities should be reliable. That is, methods and procedures should also reliably measure cognitive abilities on an individual level. This is a prerequisite for investigating the relations between different tasks in order to map out the internal structure of great ape cognition (Shaw & Schmelz, 2017; Thornton & Lukas, 2012; Volter, Tinklenberg, Call, & Seed, 2018). Finally, individual differences should be predictable. Understanding great ape cognition means that we can point to external variables that describe individual characteristics or aspects of everyday experience that induce variation in cognitive performance and development.

The prototypical study in comparative research still involves only a handful of

individuals from a single species tested with in one cognitive task (see ManyPrimates et al., 2019 for a review). Recently, a number of concerns have been voiced, questioning whether this way of conducting comparative research is suited to provide the empirical basis for inferring the great ape baseline (Farrar & Ostojic, 2019; ManyPrimates et al., 2019; Schubiger, Fichtel, & Burkart, 2020; Stevens, 2017). A key point in this criticism is that most research simply assumes that the three requirements outlined above are met without testing them empirically. The project reported here directly addresses this fundamental problem. There are, however, several notable exceptions that undertook great effort to provide a 81 more comprehensive picture of the nature and structure of great ape cognition (Beran & Hopkins, 2018; Hopkins, Russell, & Schaeffer, 2014; MacLean et al., 2014; Wobber, Herrmann, Hare, Wrangham, & Tomasello, 2014). Herrmann and colleagues (Herrmann, Call, Hernández-Lloreda, Hare, & Tomasello, 2007) tested a large sample of great apes (chimpanzees and orangutans) and human children in a range of tasks from different cognitive domains. The results indicated pronounced group-level differences between great apes and humans in the social, but not the physical domain. Furthermore, relations between the tasks pointed to a different internal structure of cognition, with a distinct social cognition factor for humans but not great apes (Herrmann, Hernández-Lloreda, Call, Hare, & Tomasello, 2010). Völter and colleagues [] focused on the structure of executive functions.

- Based on a multi-trait multi-method approach they developed a new test battery to assess memory updating, inhibition, and attention shifting in chimpanzees and human children. Overall, they found low correlations between tasks and thus no clear support for any of the structures put forward by theoretical models built around adult human data.
- Despite their seminal contributions to the field, these studies suffer from the same
 three shortcomings outlined above. First, it is unclear if the results are stable. That is, if the
 same individuals were tested again, would we see the same results and arrive at the same
 conclusions about absolute differences between species. Second, the psychometric properties
 of the tasks are unknown and it is thus unclear if, for example, low correlations between
 tasks reflect a genuine lack of shared cognitive processes or simply measurement imprecision.
 Finally, it remains unclear what causes individual differences which individual
 characteristics and experiences predict cognitive performance and development.

The studies reported below seek to solidify the empirical grounds of the great ape 104 baseline. For one-and-a-half years, every two weeks we administered a set of five cognitive 105 tasks (see Figure 1)) to the same population of great apes (N = 43). The tasks spanned 106 across cognitive domains (social cognition, causal cognition, numerical reasoning, executive 107 functions) and were based on published procedures widely used in the field of comparative 108 psychology. In addition to the cognitive data, we continuously collected data for more than a 109 dozen variables that capture stable and variable aspects of our participants' life and used 110 this to predict inter- and intra-individual variation cognitive performance. Data collection was split into two phases. After Phase 1 (14 data collection time points), we analysed the 112 data and registered the results (https://osf.io/7qyd8). Phase 2 lasted for another 14 time 113 points and served to replicate and extend Phase 1. this approach allowed us to test a) how 114 stable group level results are, b) how reliable individual differences are, c) how individual 115 differences are structured and d) what predicts cognitive performance. 116

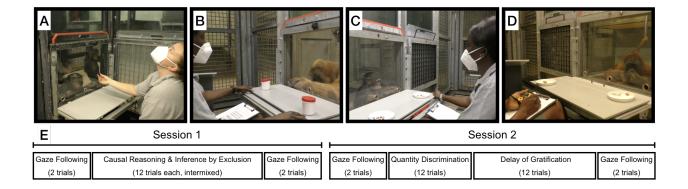

Figure 1. Setup used for the six tasks. A) Gaze following: the experimenter looked to the ceiling. We coded if the ape followed gaze. B) Causal reasoning: food was hidden in one of two cup, the baited cup was shaken (food produced a sound) and apes had to choose the shaken cup to get food. Inference by exclusion: food was hidden in one of two cups. The empty cup was shaken (no sound) so apes had to choose the non-shaken cup to get food. C) Quantity discrimination: Small pieces of food were presented on two plates (5 vs. 7 items); we coded if subjects chose the larger amount. D) Delay of gratification (only Phase 2): to receive a larger reward, the subject had to wait and forgo a smaller, immediately accesible, reward. E) Order of task presentation and trial numbers

Results 117

Stability of group-level performance 118

121

124

Group-level performance was largely stable or followed clear temporal patterns (see 119 Figure 2). The causal inference and quantity discrimination tasks were the most robust: in 120 both cases performance was clearly different from chance across both phases with no apparent change over time. The rate of gaze following declined in the beginning of Phase 1 122 but then settled on a low but stable level until the end of Phase 2. This pattern was 123 expected given that following the experimenters gaze was never rewarded – neither explicitly with food or by bringing something interesting to the subject's attention. The inference by 125 exclusion task showed an inverse pattern with group-level performance being at chance-level 126

for most of Phase 1, followed by a small, but steady, increase throughout Phase 2. These
temporal patterns most likely reflect training (or habituation) effects that are a consequence
of the repeated testing. Performance in the delay of gratification task (Phase 2 only) was
slightly variable, but within the same general range. In sum, performance was very robust in
that time points generally licensed the same group-level conclusions. The tasks appeared well
suited to study group-level performance. In the supplementary material, we report additional
analysis – latent state structural equation models – that corroborate this interpretation.

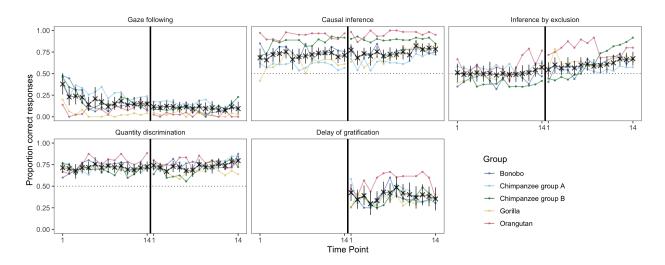

Figure 2. Results from the five cognitive tasks across time points. Black crosses show mean performance at each time point across species (with 95% CI). Colored dots show mean performance by species. Dashed line shows the chance level whenever applicable. The vertical back line marks the transition between phase 1 and 2.

Reliability of individual differences

Stable group-level performance does not imply stable individual differences. In fact, a well-known paradox in human psychology states that some of the most robust – on a group level – cognitive tasks do not produce reliable individual differences (Hedge, Powell, & Sumner, 2018). In a second step, we therefore assessed the reliability of our five tasks. For that, we correlated the performance at the different time points in each task. Figure 3

145

146

147

visualizes these raw re-test correlations. Correlations were generally high – exceptionally
high for animal cognition standards (Cauchoix et al., 2018) – with higher values for time
points closer together (Uher, 2011). The quantity discrimination was less reliable compared
to the other tasks.

What stands out in this is that *stability does not imply reliability* - and vice versa. The quantity discrimination task showed robust group-level performance above chance but relatively poor re-test reliability. Group-level performance in the inference by exclusion and gaze following tasks changed over time but was highly reliable on an individual level. Taken together, the majority of tasks was well suited to study individual differences.

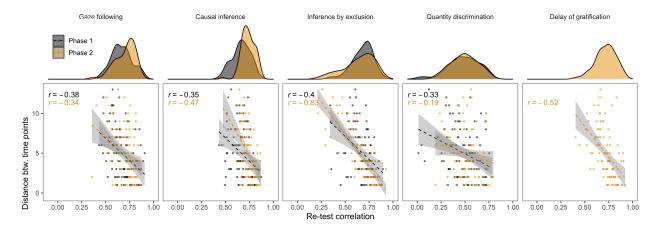

Figure 3. Top: Distribution of re-test correlation coefficients between time points for each task. Bottom: Correlations between re-test reliability coefficients and temporal distance between the testing time points.

49 Structure of individual differences

Next, we investigated the structure of these individual differences. First, we asked to
what extent individual differences reflect stable differences in cognitive abilities. We used
structural equation modelling – in particular latent state-trait models (LSTM) – to partition
the variance in performance into latent traits (*Consistency*) and states (*Occasion specificity*)
(Geiser, 2020; Steyer, Ferring, & Schmitt, 1992; Steyer, Mayer, Geiser, & Cole, 2015). In the

present context, one can think of a latent trait as a stable cognitive ability (e.g. ability to make causal inferences) and states as time-specific, variable psychological conditions (e.g. variations in performance due to being attentive or inattentive). These latent variables are measurement-error free because they are estimated taking into account the reliability of the task. In the LSTM context, reliability is the correlation between task and occasion specific test-halves. We report additional models in the supplementary material

Individual differences were largely explained by stable differences in cognitive abilities.

Across tasks, more than 75% of variance was accounted for by latent trait differences and

less than 25% by state differences (Figure 4A). The high reliability estimates show that these

latent variables accounted for most of the variance in raw test scores – with the quantity

discrimination task being, once again, an exception. The estimates for consistency and

occasion specificity were also remarkably similar for the two phases.

For inference by exclusion, we could not fit an LST model to the data from Phase 2. 167 Instead, we had to divide Phase 2 in two parts (time point 1-8 and 9-14) and estimate a 168 separate trait for each part. The estimates for the proportion of variance explained by states 169 and traits were similar for both parts (Figure 4A) and the two traits were highly correlated 170 (r = .82). Together with additional latent sate models which we report in the supplementary 171 material, this suggests that the increase in group-level performance in Phase 2 was driven by 172 a relatively sudden improvement of a few individuals, mostly from the chimpanzee B group 173 (see Figure 2). These individuals "rose through the ranks" half-way through Phase 2 and then retained this position for the rest of the study. Some of the orangutans changed in the 175 opposite direction – though to a lesser extend. 176

As the second step, we investigated the relations between latent traits. That is, we asked whether individuals with high abilities in one domain also have higher abilities in another. We fit pairwise LST models that modeled the correlation between latent traits between two tasks (two models for inference by exclusion in Phase 2). In Phase 1, the only

correlation that was reliably different from zero was that between quantity discrimination and inference by exclusion. In Phase 2, this finding was replicated and, in addition, four more correlations turned out to be substantial (see Figure 4B). One reason for this increase was the inclusion of the delay of gratification task. Across phases, correlations involving the gaze following task were the closest to zero, with quantity discrimination in Phase 2 being an exception. Taken together, the overall pattern of results suggests substantial shared variance between tasks – except for gaze following.

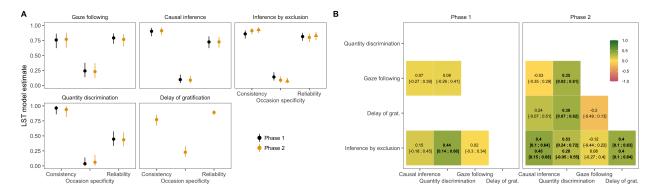

Figure 4. A. Estimates from latent state-trait model for Phase 1 and 2. Consistency: proportion of (measurement-error free) variance in performance explained by stable trait differences. Occasion specificity: variance explained by variable states. Reliability: proportion of variance in raw scores explained by the trait and the state. For inference by exclusion: different shapes show estimates for different parts of Phase 2 (see main text for details). B. Correlations between latent traits based on pairwise LST models between tasks with 95% Credible Interval. Bold correlations are reliably different from zero. Inference by exclusion has one value per part in Phase 2. The models for quantity discrimination and causal inference showed a poor fit and are not reported here (see supplementary material for details).

188 Predictability of individual differences

The results thus far suggest that individual differences originate from stable differences in cognitive abilities that might be shared between tasks. In the last set of analysis, we

sought to explain the origins of these differences. That is, we analysed whether inter- or 191 intra-individual variation in performance in the tasks could be predicted by variables that 192 capture a) stable differences between individuals (group, age, sex, rearing history, time spent 193 in research), b) differences that vary within and between individuals (rank, sickness, 194 sociality), c) differences that vary with group membership (time spent outdoors, 195 disturbances, life events), and d) differences in testing arrangements (presence of observers, 196 study participation on the same day and since the last time point). We collected these 197 predictor variables using a combination of directed observations and keeper questionnaires. 198 This large set of potentially relevant predictors poses a variable selection problem. That is, 199 we sought to find the minimal set of predictors that allowed us to accurately predict 200 performance in the cognitive tasks. We chose the projection predictive inference approach 201 because it provides and excellent trade-off between model complexity and accuracy (Pavone, 202 Piironen, Bürkner, & Vehtari, 2020; Piironen, Paasiniemi, & Vehtari, 2020; Piironen & 203 Vehtari, 2017). The outcome of this analysis is a ranking of the different predictors in terms of how important they are to predict performance in a given task. Furthermore, for each 205 predictor, we get a qualitative assessment of whether it makes a substantial contribution to 206 predicting performance in the task or not. 207

208 ... but models also included a random intercept term, capturing variance specific to
209 individuals not explained by the predictors.

210 Discussion

211 Summary

Individual differences are mostly stable across time. This matches well with the PPI results selecting stable individual differences as the most important predictors. Group not species because A and B chimps not always align and few individual per group. But also the case that a large chunk of the variance remained unexplained. Most likely this reflects

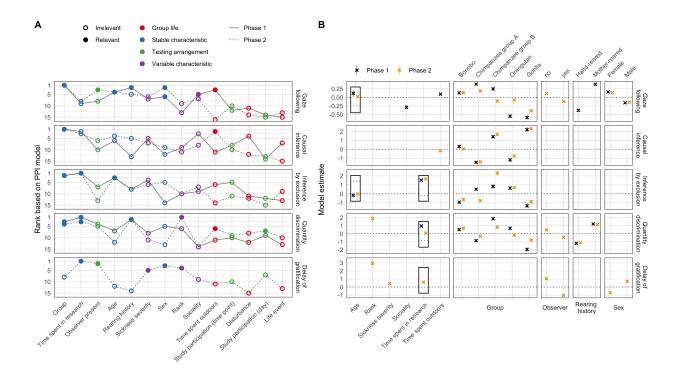

Figure 5. A. B. with 95% Credible Interval.

216 differential developmental effects.

225

performance in these tasks largely explained by stable traits - nothing that responds to daily fluctuations and small scale changes. also reflected in selected predictors

Learned something about development. we saw change over time - but this change was slow, steady and not uniform. the hypothetical argument that looms large in studies of great ape cognition fearing associative learning effects that might account for findings is simply not supported by the data. The study presented ideal conditions for associative learning to happen (same tasks, with exact same order dozens of times), yet the change we saw was slow, steady - and not the same for everyone. No doubt apes can do pure associative learning - it is just very very slow.

Systematic relations between tasks. Where do they come from? same methods (cite christoph) or same cognitive mechanisms? larger samples needed to do this systematically

and not just for 2 tasks at a time. collaboration (cite MP). Also Task based cognitive modelling would be good (cite RSApes, pragBat?)?

230 Methods
